Familial dilated cardiomyopathy

Familial dilated cardiomyopathy is a genetic form of heart disease. It occurs when heart (cardiac) muscle becomes thin and weakened in at least one chamber of the heart, causing the open area of the chamber to become enlarged (dilated). As a result, the heart is unable to pump blood as efficiently as usual. To compensate, the heart attempts to increase the amount of blood being pumped through the heart, leading to further thinning and weakening of the cardiac muscle. Over time, this condition results in heart failure.

It usually takes many years for symptoms of familial dilated cardiomyopathy to cause health problems. They typically begin in mid-adulthood, but can occur at any time from infancy to late adulthood. Signs and symptoms of familial dilated cardiomyopathy can include an irregular heartbeat (arrhythmia), shortness of breath (dyspnea), extreme tiredness (fatigue), fainting episodes (syncope), and swelling of the legs and feet. In some cases, the first sign of the disorder is sudden cardiac death. The severity of the condition varies among affected individuals, even in members of the same family.

Frequency

It is estimated that 750,000 people in the United States have dilated cardiomyopathy; roughly half of these cases are familial.

Causes

Mutations in more than 30 genes have been found to cause familial dilated cardiomyopathy. These genes provide instructions for making proteins that are found in cardiac muscle cells called cardiomyocytes.

Many of these proteins play important roles in the contraction of the cardiac muscle through their association with cell structures called sarcomeres. Sarcomeres are the basic units of muscle contraction; they are made of proteins that generate the mechanical force needed for muscles to contract. Many other proteins associated with familial dilated cardiomyopathy make up the structural framework (the cytoskeleton) of cardiomyocytes. The remaining proteins play various roles within cardiomyocytes to ensure their proper functioning.

Mutations in one gene, $TTN$, account for approximately 20 percent of cases of familial dilated cardiomyopathy. The $TTN$ gene provides instructions for making a protein called titin, which is found in the sarcomeres of many types of muscle cells, including cardiomyocytes. Titin provides structure, flexibility, and stability to sarcomeres. Titin also plays a role in chemical signaling and in assembling new sarcomeres. The $TTN$ gene mutations that cause familial dilated cardiomyopathy result in the production of an abnormally short titin protein. It is unclear how the altered protein causes familial dilated
cardiomyopathy, but it is likely that it impairs sarcomere function and disrupts chemical
signaling.

It is unclear how mutations in the other genes cause familial dilated cardiomyopathy. It is
likely that the changes impair cardiomyocyte function and reduce the ability of these
cells to contract, weakening and thinning cardiac muscle.

People with familial dilated cardiomyopathy often do not have an identified mutation in
any of the known associated genes. The cause of the condition in these individuals is
unknown.

Familial dilated cardiomyopathy is described as nonsyndromic or isolated because it
typically affects only the heart. However, dilated cardiomyopathy can also occur as
part of syndromes that affect other organs and tissues in the body. These forms of the
condition are described as syndromic and are caused by mutations in other genes.
Additionally, there are many nongenetic causes of dilated cardiomyopathy, including
viral infection and chronic alcohol abuse.

Inheritance Pattern

Familial dilated cardiomyopathy has different inheritance patterns depending on the
gene involved.

In 80 to 90 percent of cases, familial dilated cardiomyopathy is inherited in an
autosomal dominant pattern, which means one copy of the altered gene in each cell is
sufficient to cause the disorder. In most cases, an affected person inherits the mutation
from one affected parent. However, some people who inherit the altered gene never
develop features of familial dilated cardiomyopathy. (This situation is known as reduced
penetrance.) Other cases result from new mutations in the gene and occur in people
with no history of the disorder in their family.

In rare instances, this condition is inherited in an autosomal recessive pattern, which
means both copies of the gene in each cell have mutations. The parents of an individual
with an autosomal recessive condition each carry one copy of the mutated gene, but
they typically do not show signs and symptoms of the condition.

In other rare cases, this condition is inherited in an X-linked pattern. In these cases,
the gene associated with this condition is located on the X chromosome, which is one
of the two sex chromosomes. In females (who have two X chromosomes), a mutation
in one of the two copies of the gene in each cell increases the risk of developing
heart disease, but females with such a mutation may not develop familial dilated
cardiomyopathy. In males (who have only one X chromosome), a mutation in the only
copy of the gene in each cell causes familial dilated cardiomyopathy. A characteristic of
X-linked inheritance is that fathers cannot pass X-linked traits to their sons.

Other Names for This Condition

• congestive cardiomyopathy
• familial idiopathic cardiomyopathy
• FDC
• primary familial dilated cardiomyopathy
