Myostatin-related muscle hypertrophy

Myostatin-related muscle hypertrophy is a rare condition characterized by reduced body fat and increased muscle size. Affected individuals have up to twice the usual amount of muscle mass in their bodies. They also tend to have increased muscle strength. Myostatin-related muscle hypertrophy is not known to cause any medical problems, and affected individuals are intellectually normal.

**Frequency**

The prevalence of this condition is unknown.

**Genetic Changes**

Mutations in the *MSTN* gene cause myostatin-related muscle hypertrophy. The *MSTN* gene provides instructions for making a protein called myostatin, which is active in muscles used for movement (skeletal muscles) both before and after birth. This protein normally restrains muscle growth, ensuring that muscles do not grow too large. Mutations that reduce the production of functional myostatin lead to an overgrowth of muscle tissue.

**Inheritance Pattern**

Myostatin-related muscle hypertrophy has a pattern of inheritance known as incomplete autosomal dominance. People with a mutation in both copies of the *MSTN* gene in each cell (homozygotes) have significantly increased muscle mass and strength. People with a mutation in one copy of the *MSTN* gene in each cell (heterozygotes) also have increased muscle bulk, but to a lesser degree.

**Other Names for This Condition**

- Muscle hypertrophy syndrome
